2 February 2008

ABSTRACT

We present the aim and first results of the Rapid Temporal Survey (RATS) made using the Wide Field Camera on the Isaac Newton Telescope. Our initial survey covers 3 square degrees, reaches a depth of $V \sim 22.5$ and is sensitive to variations on timescales as short as 2 minutes: this is a new parameter space. Each field was observed for over 2 hours in white light, with 12 fields being observed in total. Our initial analysis finds 46 targets which show significant variations. Around half of these systems show quasi-sinusoidal variations: we believe they are contact or short period binaries. We find 4 systems which show variations on a timescale less than 1 hour. The shortest period system has a period of 374 sec. We find two systems which show a total eclipse. Further photometric and spectroscopic observations are required to fully identify the nature of these systems. We outline our future plans and objectives.

Key words: methods: data analysis – techniques: photometric – surveys – stars: variables: – stars: binaries – general – Galaxy: stellar content

1 INTRODUCTION

The intensity of stellar objects can vary on a wide range of time-scales, ranging from seconds to months to years. A large number of projects now exist whose aim is to detect such varying sources. The reasons for this are many, but include the search for extra-solar planets and interacting binary stars. Most of these surveys are sensitive to timescales longer than a day. It is only recently that such surveys have been sensitive to shorter term timescales. For instance, the $0.3^\circ \times 0.3^\circ$ survey using the Canada France Hawaii Telescope was sensitive to variations on timescales as short as ~ 8 min (Lott et al 2002). While the Faint Sky Variability Survey has a much larger survey area, it was sensitive to variations only as short as ~ 24 min (Groot et al 2003, Morales-Rueda et al 2004). In principle the SuperWasp project is sensitive to variations on timescales as short as a few mins (Christian et al 2004). However, they are sensitive to relatively bright objects, $V \sim 7\text{--}15$.

Why is it important that we extend the parameter search down to periods shorter than 10 min? Recently a new class of object has been discovered in which coherent intensity variations have been detected on timescales of ~ 10 min or less, with the shortest being 5.4 mins (see Cropper et al 2004 for a review). It is thought that these systems are interacting white dwarf-white dwarf pairs which have no accretion disc, and the observed period represents the binary

orbital period. As such, they are expected to be amongst the first sources to be detected using *LISA*, the planned gravitational wave observatory (Nelemans, Yungleson & Portegies Zwart 2004).

These systems are at the short period end of the period distribution of white dwarf-white dwarf binaries, or AM CVn systems. For orbital periods less than 80 min, the secondary (mass donating) star cannot be a main sequence star. Further, for periods shorter than 30 min, the secondary must be a Helium white dwarf (Rappaport, Joss & Webbink 1982). There are around 13 of these AM CVn systems currently known.

Theoretical predictions suggest that AM CVn systems are commonplace (eg Nelemans et al 2001). It is not clear if the discrepancy between the observed number and predicted number of systems is due to an over estimate in the predicted number or if many more systems await discovery. To help resolve this question we have started a project, the Rapid Temporal Survey (RATS), whose aim is to discover new objects which vary in a coherent manner on timescales less than ~ 1 hr. As a significant by-product of this search we expect to discover many new objects which vary on longer periods. This paper presents our strategy for discovering new AM CVn systems; the positions and light curves of those systems which we have discovered as part of our initial set of observations; a discussion regarding the nature of these sources and a brief discussion as to what these observations

imply regarding the population density of AM CVn systems and other objects.

2 OBSERVATIONS AND REDUCTION

2.1 Observational strategy

Our observations were made over 3 nights starting on 28 Nov 2003 using the 2.5m Isaac Newton Telescope on La Palma and the Wide Field Camera (WFC). The WFC consists of 4 EEV 2kx4k CCDs, with each pixel corresponding to $0.33''$ on the sky. The approximate field of view is $33' \times 33'$ (with a $11' \times 11'$ gap missing on one of the corners). The orientation of the instrument was such that our field center was located near the center of CCD 4 (see Groot et al 2003 for a schematic diagram showing the orientation of the chips).

Since our goal was to obtain photometry with the highest possible time resolution, we did not use a filter - eg they were ‘white light’ observations: since our observations were made near the zenith, differential atmospheric diffraction was reduced to a minimum. However, at the start of each observation we also obtained *BVI* images. Since we did not take observations of standard stars before every field observation, the *BVI* magnitudes reported in Table 2 are probably accurate to only ~ 0.1 mag. Our exposure times were 30 sec in duration, with another ~ 42 sec of readout time for the whole array. Each field was observed for around 2-2.5 hrs. We obtained bias frames and flat fields on each night.

2.2 Field selection

Our aim was to select fields which were close to the galactic plane so that there were as many stars in the field as possible, but not so close to the plane that crowding became a serious issue. Further, we wanted to select fields that did not contain stars brighter than ~ 10 mag, which might cause charge overflow on the CCDs. To make this selection we obtained the APM catalogue¹ for a range in galactic latitudes ($5 < |b| < 25$) and wrote a routine which optimizes the field

selections for the given sky coordinate range and the shape and size of the field of view. For an observing run lasting n nights, our optimization routine finds the same number (n) of fields around 4 positions in the sky that pass close to the zenith during the night with about 2 hr spacing.

This is done using an algorithm that first places n random fields in the sky in a 5×5 degree box centered around a given pointing. Then a simulated annealing based optimization routine is used to find a combination of n non-overlapping pointings within this 5×5 degree box. The optimization tries simultaneously to maximize the number of $V=15$ -20 mag stars and minimize the number of brighter stars included. There is also a hard limit, so that no stars brighter than $V=10$ mag should appear in any of the fields. So, as a result we will get, for each night, 4 fields per night that are observable for around 2hr close to the zenith after each other, thus filling all the nights optimally.

2.3 Data Reduction

A series of ~ 100 -120 30 sec exposures were made of each field: auto-guiding was used so there is no large x, y shift between frames. For each chip we flat-fielded and bias subtracted each image. The analysis (for each chip) consisted of following steps: the first 5 frames of each field were combined in order to form a ‘master’ image of the field. This master image was then searched for all the sources above a 5σ detection limit. Next, we determined for each of the remaining frames an accurate image shift in relation to the master image. This was done in order to be able to use small enough apertures for light curve extraction, thus maximizing the S/N ratio for the photometry. In practice, this was achieved by using the positions of a couple of bright (but not saturated) stars. After having determined (and applied) the shifts for individual images, we obtained quasi-differential photometry using the median brightness of the sources in each frame as a comparison (to remove any variations in the sky transparency) – this was done for all the images of the field. In total around 33000 stars were detected in our survey which covered a total of 3 square degrees.

All the resulting light curves were analysed and those which had bad magnitude values or errors above 0.1 mag or non-detections in any frame, were discarded. This reduced the total number of light curves by around 2000. All the ‘good’ light curves were analysed using a Lomb-Scargle period search algorithm, and those light curves which showed a significant peak in their power spectrum were flagged for closer inspection. The significance of the highest peak in each power spectrum was estimated in the following manner. First, we took the highest peak power value and mean power value for each power spectrum. Then we defined the significance statistic of the highest peak in the power spectrum by computing the ratio of it to the mean power value. The final selection of ‘interesting’ variable targets was carried out manually. For each chip we produced a plot of apparent magnitude against the significance statistic for all the stars. When the overall number of fields is not too large (as in the case here), such a plot provides a convenient way of identifying the likely variables in each field.

To test our procedure we selected the field of RX J0806+15, the 5.4 min ultra-compact binary system. Its brightness variation is highly stable with a peak-to-peak

¹ <http://www.ast.cam.ac.uk/~apmcat>

Figure 1. The results of our routine to detect sources varying in their intensity using the field of the ultra-compact binary RX J0806+15 as a test case. The magnitudes have been scaled so they are approximately that of V mag and higher significance values imply strong variability. Our routine clearly identifies RX J0806+15 as being highly variable.

modulation of ~ 0.3 mag in white light (Ramsay, Hakala & Cropper 2002). We ran our data analysis procedure in the manner outlined above. For each star in the field we plot the significance of the highest peak in its power spectra (as defined above) as a function of brightness in Figure 1. RX J0806+15 was easily picked up by our routine. We are therefore confident that we can detect sources which have coherent variability with amplitudes of ~ 10 percent or lower.

For those sources identified as being significantly variable, we used *autophotom* (Eaton, Draper & Allan 2003) to obtain ‘optimal’ photometry for each source together with suitable comparison sources. Whilst our procedure for identifying variable sources is relatively simple, we have demonstrated that it will detect targets such as RX J0806+15 with ease. However, it is probable that additional variable sources still await detection using a more sophisticated detection routine.

2.4 Source positions

To determine accurate positions for our variable sources, we compared our fields with the Digital Sky Survey images and the Hubble Guide Star Catalogue. We typically used 8 reference stars for each chip. We then compared the x, y position of each reference stars in our images and used *astrom* (Wallace & Gray 2002) to obtain J2000 co-ordinates for each of our sources. The residuals to the fits were typically $\sim 0.5''$. We searched for known sources in the SIMBAD database using a aperture of radius $10''$ centered on our source positions: there were no known sources at these positions. All our sources are therefore newly discovered variable sources.

3 INITIAL RESULTS

Out of the 33000 stellar objects in our survey, we have identified 46 which have showed evidence for significant variability.

Figure 2. Top panel: The number of variable source discovered in our survey as a function of magnitude. Bottom panel: The percentage of variable sources as a function of the number of stars in a magnitude range.

Their position, V mag and colour and the characteristics of their light curves are shown in Table 3.

We show in Figure 2 the actual number of sources which varied as a function of apparent brightness and also the fraction of sources which were found to be variable as a function of brightness. We find variable sources in the range $15 < V < 22$, with an approximately uniform spread in the number of sources as a function of apparent brightness. Although, the number of sources in the bins are relatively small, we note that the fraction of sources which are variable is not uniform, showing a peak in the bin $15.5 < V < 16.5$. We discuss one possible reason for this in §4.

The light curves of our 46 variable sources are shown in Figures 3–5. They can be split up into 5 broad categories: those showing sinusoidal-like variations; coherent variations; eclipse-like behaviour; flaring; and more irregular behaviour. We now go onto discuss various objects in more detail.

3.1 Objects varying on periods of less than 1 hour

The main goal of this project is to discover sources which vary in their intensity in a coherent manner on timescales of ~ 1 hour or less. We have discovered one source with a coherent period of 374 sec, 2 systems showing sinusoidal variations on timescales of ~ 1 hour, one which shows a variation on 40 or 80 mins and one with a possible variation on a period of 75 mins.

The system with the shortest period was RAT

**Figure 3.** Light curves of all interesting sources.

Figure 4. Light curves of all interesting sources (cont).

Figure 5. Light curves of all interesting sources (cont).

Figure 6. White light data of RAT J0455+1305 folded on the best fit period of 374 sec.

J0455+1305 which was found to vary on a period of 374 sec and an amplitude of 0.13 mag. The source is detected in the USNO-B1 Catalogue, but not in the *ROSAT* all-sky survey. The folded light curve appears sinusoidal (Figure 6). The shape and amplitude are virtually identical to the discless ultra-compact binaries mentioned in §1. On the other hand pulsating white dwarfs and sub-dwarf pulsators (EC14026 stars) also show such coherent modulations. Dedicated observations of this object will be presented in a future paper.

The two systems which show sinusoidal variations on periods close to 1hr, RAT J0455+1254 and RAT J0807+1507, have amplitudes of 0.06 and 0.25 mag respectively. The latter has a light curve which shows clearly peaked maxima. If their periods are indeed close to 1 hr, then this would rule out them being W UMa systems - contact binaries which have orbital periods in the range 0.2–1.5 days.

RAT J0449+1756 shows clear variations with an amplitude of ~ 0.04 mag. It is unclear whether there is a modulation on a period of 40 or 80 min. Unfortunately this object was just off the chip edge when we made the *BVI* images. It was, however, detected in the 2MASS survey: it shows

JHK colours which are blue. Its blue colour and its period are similar to that of the AM CVn systems: in this case, it would be expected to show strong Helium lines in emission in its optical spectrum.

3.2 Objects showing eclipse-like features

There are three sources which show eclipse-like behaviour: RAT J0740+2340 (a total eclipse of depth 0.1 mag), RAT J2310+3414 (an eclipse-like feature of depth ~ 0.2 mag) and RAT J2257+3424 (a partial eclipse with depth 0.2 mag). Each system shows red optical colours out of eclipse (cf Table 2) and were all detected in the 2MASS survey²: RAT J0740+2340 has colours of a M4-5 dwarf star while RAT J2257+3424 is consistent with an early K dwarf star. In the case of RAT J0740+2340 the white light and *BVI* images show a slight elongation of the source implying the colours for this source may be contaminated by a close ‘companion’ star. RAT J2310+3414 shows infrared colours, $(H-K)=0.52$, $(J-H)=-0.08$, which are not consistent with that of main sequence stars.

The eclipse of RAT J0740+2340 takes ~ 20 min to descend into and out of eclipse. The total duration of the eclipse is ~ 65 min (half eclipse depth). The rather low eclipse depth rules out it being a cataclysmic variable which would show a much greater eclipse depth. RAT J2257+3424 maybe an Algol system in which we have detected the secondary eclipse.

As the shape of the eclipse profile of RAT J0740+2340 closely resembles one produced by a planetary transit, we have studied its properties further. Assuming the eclipse is produced by a transiting planet, we can work out some preliminary parameters for the system. Firstly, the 0.1m depth of the eclipse implies that the radius of the planet

Table 2. Those sources discovered in the first reduction of our INT/WFC survey data. We quote the period of any source showing periodic behaviour, together with the change in white light magnitude and the main characteristic of the light curve (sin: sinusoidal in shape; ecl: eclipse; shortp: short period variability). *RAT J0208+3605 is $\sim 1''$ distant from another source from which it was not possible to fully resolve: the quoted magnitudes are the combined.

has to be ~ 0.3 of the stellar radius. Secondly, the ratio of ingress/egress lengths to the duration of the total part of the eclipse implies that the transit occurs at an apparent stellar latitude of about 30° .

Some preliminary spectra of RAT J0740+2340 show that the star is of very late spectral type. Assuming a M4-6V spectral type, this would imply a stellar radius of $\sim 0.3 R_\odot$ and planetary radius of about 70000 km, i.e. the same as Jupiter. Using the stellar radius and the implied transit latitude together with the FWHM eclipse duration yields

an orbital velocity of 90 km/sec, which in turn leads to an orbit of roughly 3 days. This is similar to that observed in a handful of systems (eg Mazeh, Zucker & Pont 2005). However, further observations are required to confirm the orbital period of this object.

3.3 Objects showing longer term variations

Approximately half of our newly discovered sources show sinusoidal or quasi-sinusoidal intensity variations with periods

greater than ~ 1 hr. Sources which exhibit these characteristics include pulsating stars such as δ Scuti stars, and the W UMa and Algol binary systems.

δ Scuti stars show intensity variations on timescales between 30 min and ~ 8 hrs, with amplitude variations less than ~ 1 mag. However, these systems tend to show asymmetric light curves, with the rise to maximum taking a shorter time than the descent from maximum. We have discovered one candidate δ Scuti system: RAT J0305-0036 shows an asymmetric light curve; a period of ~ 2 hrs and an amplitude of ~ 0.3 mag.

W UMa systems are well known systems, being thought to account for 1 in every 500 stars (Rucinski 2002) and show orbital periods between 4 hrs – 1.5 days. Other systems include binary systems in which the mass losing star is irradiated by the mass accreting star: this results in the companion star being apparently brighter when it is viewed face-on compared to when we observe it from the rear. In recent years it has become clear that many sub-dwarf B stars (sdB) are in such binary systems: these stars are Extreme Horizontal Branch stars which have Helium cores and only a thin layer of Hydrogen on their surface (eg Maxted et al 2002). The companion star in these systems could be main sequence stars, white dwarfs or even brown dwarf stars. Those systems with white dwarfs have potentially wide astrophysically significance since they maybe SN Ia progenitors (Maxted, Marsh & North 2000). We expect that many of our newly discovered sources will be contact and non-contact binaries.

3.4 Flare sources

We detected two flare like objects in our survey. RAT J0456+1254 showed a 0.25 mag flare while RAT J0806+1540 showed a ~ 1 mag flare. RAT J0456 was detected in all three *BVI* bands while RAT J0806 was detected only in the *I* band. The former has colours consistent with a main sequence M5/M6 star (Pickles & van der Kruit 1990), which using the absolute magnitude relation in Allen (1973) gives a distance of ~ 725 pc for a M5V star and ~ 380 pc for a M6V star. RAT J0806+1540 is therefore likely to be an even later type dwarf star or more distant than RAT J0456. M dwarf stars are known to show prominent flare behaviour.

3.5 Minor Planets

As expected a number of minor planets were detected: a total of 16 were identified. Their positions were determined for 3 epochs using the procedure in §2.3 : these were passed to our minor planet colleagues based at the University of Helsinki. They determined if there were any known minor planets at positions at these epochs - 5 were not previously known.

To accurately determine the orbit of a minor planet, and therefore give rise to a designation for that system, positions have to be determined on several nights. Unfortunately, since the systems were not detected until after the observing run was over, we did not get these positions. For future surveys we will run our source detection software for each field in near real-time. This will allow any new minor planet to be followed up on a subsequent night.

4 DISCUSSION & SUMMARY

We have presented the first results of our Rapid Temporal Survey which covered 12 INT/WFC fields, giving a total sky coverage of approximately 3 square degrees. Our survey explores a new parameter space - namely searching for objects which show intensity variations on timescales as short as a few mins. Using our relatively simple algorithm to detect such sources we have discovered 46 sources which showed variability on timescales between 374 sec and 4–5 hrs. For sources which vary on periods longer than ~ 8 hrs, it is probable that we would not have identified them as such in our short observing window. To determine the nature of the new variable sources, plans are in place to obtain followup photometry and spectroscopy.

We estimate that our white light images reached a depth corresponding to an equivalent $V \sim 22.5$ (the exact depth depends on the colour of the source). The distance to the edge of the galaxy on the far side of the galactic center in the plane is ~ 22.5 kpc. For a galactic latitude of 20° (typical of fields observed in our initial survey) we can detect every star with a spectral type earlier than $\sim K2$ out to the edge of the galaxy. However, the scale height of the galaxy is of the order of 200 pc. This implies that for stars within 3 scale heights of the galaxy we can detect every star as faint as $\sim M5$.

We noted in §3 that there was a peak in the percentage of objects which were variable in the range $15.5 < V < 16.5$. If we assume that at a distance of 3 scale heights the number of additional sources which we detect is negligible then that implies a distance of 1.7 kpc for galactic latitude of 20° . For $V=16$ and a distance of 1.7 kpc this implies a depth of $M_V=6$. We note that W UMa systems have a range in absolute magnitude of $M_V=2-6$ with systems with the shortest orbital periods (0.2 days) being intrinsically fainter than longer period systems. We suggest that if the peak in the distribution of percentage of objects which are variable is real (to be confirmed in the extension of the survey) then it is due to W UMa systems: after $V \sim 16$ there are no more of these systems to discover. This is consistent with the suggestion that a significant fraction of our newly discovered systems are W UMa systems.

One of the main science goals of this project is to search for AM CVn systems. Although this paper presents only our initial findings, we have found only one or two (at most) systems which could, with further observations, be classed as candidate AM CVn systems. How many were expected from population synthesis models? Nelemans et al (2001) predicted a space density of $2.1 \times 10^{-4} \text{ pc}^{-3}$ which was revised down-wards by around 60 percent by Nelemans, Yungelson & Portegies Zwart (2004). The distance that we can detect such systems is dependent on their absolute magnitude which in turn is dependent on their orbital period. For longer period systems such as GP Com, $M_V \sim 12$, implying we could detect them out to a distance of 1.6 kpc (we expect to detect systems with shorter orbital periods out to greater distance). If we take a uniform distribution of AM CVn systems, then in a 3 square degree survey the above space density predictions imply around 150 systems (with an uncertainty of at least 2). However, Nelemans et al (2004) made an investigation regarding selection effects and found that for an optical limit of $V = 20$ only approxi-

mately 1 percent of systems with orbital periods less than 25 mins would be detected as an AM CVn system in the optical band, implying only 1–2 systems in our 3 square square degree survey. Since our survey extends to a fainter optical limit and work is needed to compare the overall space density at different orbital periods, it is too early to make definitive conclusions regarding the comparison of theoretical predictions and observed space density estimates.

In conclusion, we have found by exploring a new parameter space around 46 new objects which have not before been identified as variable sources. How does this discovery rate compare with other surveys? Mukadam et al (2004), for instance, found 35 pulsating white dwarfs in 125 nights of observing time. We have discovered one pulsating star in 3 nights, giving a similar discovery rate. However, we have found many new objects in addition to this one very short period system. More observational data is needed to confirm their nature: this work is in hand, and our results will be presented in a followup paper.

5 ACKNOWLEDGMENTS

PJH is an Academy of Finland research fellow. Observations were made using the Isaac Newton Telescope Wide Field Camera on La Palma. We gratefully acknowledge the support of the observatory staff. We thank Mikael Granvik for following up our minor planet detections and Mark Cropper for useful discussions. This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France.
